Received February 12; accepted March 9, 1992

Abstract. — New grids of stellar evolutionary models covering the range of 0.8 to 120 $M_{\odot}$ have been computed for metallicities $Z = 0.020$ and $Z = 0.001$. The models use the new opacities by Rogers & Iglesias (1991) and by Kurucz (1991) at low T . The consequent changes in the solar helium content, in the mixing length ratio and in the overshooting parameter are taken into account after careful calibrations. Important physical ingredients as the nuclear reaction rates and the neutrino loss rates have been updated. The ionization of the main heavy elements is calculated in details. An improved treatment of the optically thick envelope of WR stars is made on the basis of the CAK theory (cf. Kudritzki *et al.* 1989). Results of the models are given in a compact way at corresponding evolutionary stages in each model. In addition to the tables, we shortly present some general results on the tracks in the HR diagrams, the lifetimes in the H-, He-, C-burning phases and on massive and WR stars.

Key words: stars: evolution — mass loss — supergiants — Wolf Rayet

1. Introduction.

Extensive and accurate grids of stellar models at various metallicities Z are a basic tool for several astrophysical objectives: studies of star clusters, population synthesis, stellar nucleosynthesis and chemical evolution, etc... For such purposes, grids covering a wide range of masses are needed, with data given at corresponding evolutionary stages in order to permit reliable interpolations for population synthesis and other purposes.

Several grids of stellar models were made previously by others and us. However within the last few years, a number of improvements have occurred, which lead us to calculate new grids for stellar evolution. We list here all the modifications with respect to our previous works (cf. Maeder & Meynet 1989).

- 1) New radiative opacities by Rogers & Iglesias (1991) have been included for the available range of X , Y , Z . The changes with respect to the Los Alamos 1977 opacities are quite large: they typically amount to a factor of 3 at 300000 K for solar metallicity. Most outputs of stellar evolution are significantly modified by these opacity changes, in particular surface parameters (L , R , T_{eff}), envelope structure and pulsation properties. These various effects were well presented by W. Däppen *et al.* in the report of IAU Comm. 35 of the 1991 IAU General Assembly (cf. Bergeron 1992). Sev-

eral astrophysical effects were suggesting over recent years that the opacity should sizeably increase.

- 2) At low T , i.e. below 6000 K, radiative opacities by Kurucz (1991) also including the main molecular lines have been accounted for.
- 3) The change of opacities leads us to revise the initial He- content of the Sun to $Y = 0.229$ for $Z = 0.0188$.
- 4) The average relative ratio $\Delta Y / \Delta Z$ of helium to metal enrichment consistent with the above solar values is about 3, which is in agreement with values recently found by Pagel (1992) and implies a revision of the He-content of all Z models.
- 5) Changes in nuclear cross-sections have been made. Of major importance is the choice of the rate for the $^{12}\text{C}(\alpha, \gamma)^{16}\text{O}$ reaction which greatly affects the He-burning phase, in particular the extension of the blue loops. In this work we took the rate as given by Caughlan *et al.* (1985), compatible with the recent theoretical computation of Descouvemont (1989). Other changes have also been taken into account (cf. Landré *et al.* 1990; Caughlan *et al.* 1988).
- 6) New rates for neutrino losses have been included (cf. Itoh *et al.* 1989).
- 7) Convection parameters l/H_p and the overshooting distance change as a result of the increased opacities (cf. also Stothers & Chin 1991a).
- 8) We have also included the detailed treatment of the partial ionization for the main heavy elements in the

Send offprint requests to: A. Maeder, Geneva Observatory

code and we calculate all the corresponding thermodynamic quantities.

- 9) Changes in the algorithms used for the computation of chemical changes have been brought about in order to treat more accurately convective cores, particularly when overshooting is significant. This leads to a reduction of some timescales with respect to Maeder & Meynet (1989) as mentioned in Sect. 4 below and we apologize for the resulting changes. Interestingly enough, this re-examination enabled us to put the finger on several critical points which influence the timescales. They will be discussed in a further paper.
- 10) The optically thick wind of WR stars is treated in the framework of the modified Castor, Abbott and Klein theory (cf. Castor et al. 1975; Kudritzki et al. 1989). This enables us to satisfactorily calculate the T_{eff} and radii of WR stars, in view of investigating their mass - luminosity - mass loss rate - T_{eff} - He content - C/O ratio relations.

Apart from the changes mentioned above there were a number of other improvements brought about in recent years (cf. Maeder & Meynet 1989), regarding the equation of state, the metallicity dependence of the mass loss rates $\dot{M}$, the values of $\dot{M}$ for WR stars, etc... Sect. 2 gives more information on the physical ingredients. Section 3 presents the contents of the tables, while a few global results are given in Sect. 4.

The present grids at $Z = 0.020$ and $Z = 0.001$ will be followed by further grids at other metallicities, in particular at $Z = 0.040$ and 0.008 with the normally associated helium contents.

2. Physical ingredients of the models

2.1. OPACITY

The radiative opacity tables of Rogers & Iglesias (1991) from $Z = 0.0001$ to $Z = 0.03$ for $X = 0.7$, 0.35 and 0.0 have been included. This is major change for the models, particularly around $\log T = 5.5$, where the differences with respect to previous opacities at $Z = 0.02$ amount to about a factor of 3. For metallicities higher than $Z = 0.03$, which occur in the core during the He-burning phase, we use the tables of Huebner et al. (1977). We have completed the tables of Rogers & Iglesias (1991) at low temperatures from 6000 K to 2100 K with the atomic and molecular opacities of Kurucz (1991).

Following Rogers & Iglesias (1991), all the tables are organized differently from what was made in previous works. Instead of rows and columns of constant temperature and density, we use temperature and a variable R , where $R = \rho/T_6^3$, (let us recall that R would be constant for a polytrope with $n = 3$, or in other words for a star with a constant ratio of radiation to gas pressure). The use of R and T_6 as interpolation variables minimizes the

interpolation errors. Rogers & Iglesias (1991) also show that the quadratic interpolation scheme gives the minimal interpolation errors in most situations. Therefore we use a quadratic interpolation in R , T_6 , X and Z in all cases except for $Z > 0.03$ where we proceed linearly.

2.2. HELIUM ABUNDANCES

The opacities critically influence the determination of the helium mass fraction Y in the Sun. With the low opacity data by Cox & Stewart (1970), the Y value required to account for the solar L at the solar age of 4.57×10^9 y was 0.25 (cf. Bahcall et al. 1982). With the slightly larger opacities from the Los Alamos Opacities Program (cf. Huebner et al. 1977), the He content of the Sun was found to be $Y = 0.28$ (cf. Lebreton & Maeder 1986). Now, the larger opacities by Rogers & Iglesias (1991) and by Kurucz (1991) at low T again lead to an increase in Y . The physical reason is that if the opacities of heavy elements increase for a fixed amount Z , one has to dilute these heavy elements into a mixture containing more helium and less hydrogen (since helium is less opaque than hydrogen) in order to be able to satisfy the requirements about solar age and luminosity. Test models made with $Z = 0.0188$, the metallicity of the Sun (cf. Anders & Grevesse 1989), have been performed and values of $X = 0.6822$, $Y = 0.299$ have been found to perfectly match the solar luminosity. This higher He-value is consistent with the expected trend. It is also quite in agreement with recent results by Guenther (1992).

Interestingly enough, if we consider a cosmological helium $Y_p = 0.24$ (cf. Audouze 1987), we see that the present Y value of about 0.30 for the Sun is consistent with a relatively high ratio $\Delta Y/\Delta Z \simeq 3$ of helium to metal enrichment during galactic evolution (cf. Pagel 1982). In summary, for various opacity sources, the solar requirements imply different solar helium content $Y_\odot$, to which different solar $\Delta Y/\Delta Z$ ratios are associated:

Cox & Stewart (1970)	$Y_\odot = 0.25$	$(\Delta Y/\Delta Z)_\odot = 0.53$
Los Alamos (1977))	$Y_\odot = 0.279$	$(\Delta Y/\Delta Z)_\odot = 2.1$
Rogers & Iglesias,		
Kurucz (1991)	$Y_\odot = 0.299$	$(\Delta Y/\Delta Z)_\odot = 3.1$

Thus, for our sequence with a typical metallicity $Z = 0.020$, it seems advisable to use a helium content of $Y = 0.30$ rather than the former value of 0.28 or 0.25 and this introduces some changes in the models. For other metallicities Z , the initial helium content is fixed by taking $Y = Y_p + (\Delta Y/\Delta Z)Z$ with a $\Delta Y/\Delta Z$ ratio of 3. In order to be consistent, we have taken for the heavy elements the relative ratios (cf. Anders & Grevesse 1989) used in the opacity tables by Rogers & Iglesias (1991).

2.3. NUCLEAR REACTIONS, SCREENING, NEUTRINOS.

For hydrogen burning, the pp chains and CNO tri-cycle are calculated in details and the evolution of the main nuclear species is followed explicitly (see Maeder 1983). For helium burning the same reaction network as in Maeder & Meynet (1987) was used supplemented with the $^{17}\text{O}(\alpha, n)^{20}\text{Ne}$ reaction which is active at the beginning of this nuclear phase and is responsible for the transformation of the quasi totality of ^{17}O left by the hydrogen burning into ^{20}Ne . For the carbon burning phase we took into account the following reactions: $^{12}\text{C}(^{12}\text{C}, \alpha)^{20}\text{Ne}$, $^{12}\text{C}(^{12}\text{C}, p)^{23}\text{Na}$, $^{12}\text{C}(\alpha, \gamma)^{16}\text{O}$, $^{16}\text{O}(\alpha, \gamma)^{20}\text{Ne}$, $^{20}\text{Ne}(\alpha, \gamma)^{24}\text{Mg}$ and $^{23}\text{Na}(p, \alpha)^{20}\text{Ne}$. There the abundances of the protons and alpha particles are supposed to have reached equilibrium.

With the exception of three reactions (see below), all the reaction rates are taken from Caughlan & Fowler (1988). For the $^{12}\text{C}(\alpha, \gamma)^{16}\text{O}$ reaction, we took the rate from Caughlan *et al.* (1985) which is enhanced by about a factor 3 with respect to the older value (cf. Fowler *et al.* 1975). Even if in their last compilation, Caughlan & Fowler (1988) give a rate very close to the low 1975 value, the use of the enhanced rate appears justified by the following facts:

- 1) Recent experimental determinations by Redder *et al.* (1987), Plaga *et al.* (1987), Kremer *et al.* (1988), essentially confirm the high cross section first found by Kettner *et al.* (1982).
- 2) Theoretical computations performed by Descouvemont (1989) also predict an enhanced rate compatible with the one given by Caughlan *et al.* (1985).
- 3) The comparison of the abundance observations of supernova 1987A with computations of explosive nucleosynthesis shows (cf. Thielemann *et al.* 1990) that the 1975 and 1988 values of the cross section of $^{12}\text{C}(\alpha, \gamma)^{16}\text{O}$ by the Fowler group are clearly too low.

For these reasons, we choose in this work the enhanced rate as given by Caughlan *et al.* (1985). For the two reactions $^{17}\text{O}(p, \gamma)^{18}\text{F}$ and $^{17}\text{O}(p, \alpha)^{14}\text{N}$ we took the more recent rates given Landré *et al.* (1990), which are found to be substantially larger than previously thought, indicating a much larger destruction of ^{17}O during hydrogen burning. For all these reactions, when the cross-sections are uncertain (factor 0-1 in Caughlan & Fowler 1988, or 0.2-1 in Landré *et al.* 1990) we take, as recommended, the intermediate factor 0.1, 0.5 respectively. The screening factors are computed according to Graboske *et al.* (1973). In radioactive weak interactions such as beta decays and electron capture the neutrino energy losses are computed according to the rule given by Fowler *et al.* (1975). The neutrino energy loss rates due to pair, photo and plasma processes are taken from Itoh *et al.* (1989). The neutrino pair bremsstrahlung from degenerate electron gas is taken into account (Festa & Ruderman 1969) allowing for cor-

rection factor of Dicus *et al.* (1976) to take into account neutral current effects.

The way chemical changes due to secular evolution are computed in an evolutionary code plays a crucial role for the correct determination of basic physical characteristics as the duration of the different nuclear burning phases. In this work, modifications have been brought to the algorithm which computes the changes of chemical composition with the aim to obtain a better consistency between the physical and chemical structure of the models. At this point it is worth describing very briefly the procedure followed. The composition changes are computed in an implicit manner. Let us start from the situation where we have for the model at the time t^n , the correct structure S^n (profiles of the pressure, temperature etc...) and chemical composition C^n . To compute these same quantities for the time $t^{n+1} = t^n + \delta t$, firstly an initial estimate of the chemical composition C_0^{n+1} is made, then the approximate solution for the structure is improved during the first iteration (use of the Henyey method), giving S_1^{n+1} . These better profiles of pressure and density are then used to compute a new chemical composition C_1^{n+1} . The same scheme is iterated as long as necessary to obtain the desired accuracy. The main point here is the fact that the nuclear reaction network is resolved at each iteration in contrast with the usual procedures where chemical composition is adjusted only once, either at the beginning or at the end of the iterations resolving the structure. The procedure proposed here maintains a higher level of consistency between the structure and chemical composition at each iteration. In this way changes of the chemical composition immediately interact on the structure through the quantity of energy released by the nuclear reactions. The structure in turn directly influences the changes of the abundances through the nuclear reaction rates and the size of the convective core. This consistency between the chemical and physical structure is particularly important during the phases when the location of the border of the convective core is very sensitive to small physical changes. Even if this method is expensive in computing time it does not appear to be prohibitive for not too extended reaction networks, especially in regards of the improvements brought to the internal consistency of the models. Let us mention here that the use of an insufficient numerical scheme had as a consequence that the models of 1.3 to $2M_{\odot}$ computed with overshooting by Maeder & Meynet (1989), although their structure was correct, had a wrong scale of time.

2.4. IONIZATION.

Partial recombination for H, He, C, O, Ne and Mg is treated in the equation of state, which is important for WR stages. This is done by iteratively solving the Saha equation as described in Cox & Giuli (1968). Only the

ground state contribution to the partition function has been included (Sparks & Fischel 1971) neglecting excited states, which is known to be a good approximation according to Unsöld (1955) and Sackmann & Boothroyd (1985). Note that the dominant effect of partial ionization lies in the opacity, which already takes partial ionization of all elements including excited states into account.

2.5. CONVECTION PARAMETERS.

The value of $\alpha_p = l/H_p$, the ratio of the mixing length to the pressure scale height is also very sensitive to the opacities. The adjustment of α_p can be made on the T_{eff} of the red giants and on the T_{eff} of the Sun. For red giants, we use the average locations of the red giant branch of more than 75 clusters, as summarized in Figure 2 by Maeder & Meynet (1989). We have made test models for $15 M_\odot$, $5 M_\odot$, $3 M_\odot$ and $1.5 M_\odot$ and different values of α_p . The best fit is obtained for $\alpha_p = 1.6 \pm 0.1$, which remarkably well reproduces the red giant branch for a wide range of clusters, from old ones like M67 to young stellar associations, i.e. over a range of 5 decades in luminosities.

Very interestingly, the value of $\alpha_p = 1.6$ also very well reproduces the solar temperature for the assumed solar composition $X = 0.6822$, $Z = 0.188$. It is noticeable that the mixing length theory, despite its great simplicity, is able with a single parameter to account for the stellar radii over such large range of different physical conditions. Also we may mention that a value of $\alpha_p = 1.6$ has been found by Guenther (1992) when at low T the Kurucz opacities are used, as we do here for complementing Rogers & Iglesias opacities.

For red supergiants with luminosities brighter than about $M_{\text{bol}} = -8.5$ (i.e. $M > 25 M_\odot$), the structure of the outer convective envelope is complex. It consists of thin outer gaseous layers floating upon a radiatively supported zone as shown by many authors (cf. Underhill 1949; Mihalas 1969; Kutter 1970; Bisnovaty-Kogan & Nadyoshin 1972; Stothers & Chin 1973; Maeder 1987, 1992). We follow here the treatment by Maeder (1987) which includes turbulent pressure, acoustic flux and a density scale height (cf. Stothers & Chin 1990). Indeed, the acoustic flux seems to be the dominant mode of energy transport in the very outer convective zone. Attempts are now being made by Meynet to treat the complex hydrodynamic situation of red supergiant envelopes with a hydrodynamic code.

The question could be raised whether the overshooting parameter, which so critically influences all outputs of stellar evolution, is not an artefact of past insufficiencies in the opacities. The question has recently been addressed by Stothers & Chin (1991a), who show that the overshooting distance for convection is likely not larger than $0.2 H_p$.

We recall that some authors have supported values as large as 1-2 pressure scale heights. Here we follow our

preferred approach. On the basis of 65 clusters and associations of all ages and well discussed for membership, reddening, distance, binarity and peculiarities, we established the location of the upper envelope of the main sequence and examined which value of the overshooting distance gives the best fit (cf. Maeder 1976; Mermilliod & Maeder 1986). With previous opacities, an overshooting distance of $(0.25 - 0.30) H_p$ was found to fit several observational constraints. With the new opacities a value of $d_{\text{over}}/H_p = 0.2$ was shown to give the best fit over the range from 1.25 to $25 M_\odot$. The situation is illustrated in Figure 3. These results confirm that the new opacities lead to a slight reduction of the overshooting parameter (cf. Stothers & Chin 1991ab). We do not find that differences due to opacities are such as to reduce the overshooting distance to zero, but we confirm (once more) that this phenomenon is likely moderate.

2.6. MASS LOSS RATES.

Here we follow the general procedure described by Maeder (1990). Namely, we take the mass loss rates $\dot{M}$ given by de Jager *et al.* (1988; cf. also Nieuwenhuijzen & de Jager 1990) for stars throughout the HR diagram except the WR stars. We adopt a scaling of mass loss rates with metallicity as given by the models of Kudritzki *et al.* (1989), i.e. $\dot{M} \sim Z^{0.5}$. For WR stars, there is no indication yet about a dependence of $\dot{M}$ -values on initial Z . However, we adopt the $\dot{M}$ vs. mass relation found by Langer (1989) for WNE and WC stars, i.e. respectively $\dot{M} = (0.60 - 1.00) \times 10^{-7} (M/M_\odot)^{2.5}$ in solar mass per year. For WNL, the average mass loss rate of 4×10^{-5} is adopted (cf. Conti 1988). There is no evidence for WNL stars about a dependence of $\dot{M}$ on luminosity or mass, although such a relation would not be so surprising.

Most outputs of massive star evolution critically depend on the mass loss rates, as is well known. In order to broaden the comparison basis and to illustrate the effects of different mass loss rates, we have computed a second set of models with masses 120, 85, 60, 40, 25, and $20 M_\odot$ at $Z = 0.020$ (Tabs 1A to 6A) and mass loss rates increased by a factor of 2 in post MS stages. For these masses the mass loss rates are the largest and most uncertain and also have the largest effects. The resulting changes in tracks and lifetimes are discussed in Sect. 4.2.

2.7. EXTENDED ATMOSPHERES.

Different possible definitions of radii and effective temperatures in stars with extended atmospheres have recently been reviewed by Baschek *et al.* (1991). To account for the non-negligible optical thickness of the winds of Wolf-Rayet stars a simple correction-scheme to determine an effective temperature was adopted (Langer 1989; Maeder 1990), assuming the standard velocity law

$$v(r) = v_{\infty} \left(1 - \frac{R}{r}\right)^{\beta}.$$

So far these corrections have been applied considering pure electron scattering opacity in the wind. The effective temperature T_{eff} is defined by the Stefan-Boltzmann law through the luminosity and an effective radius R_{eff} , which is defined as the optical-depth radius with $\tau(R_{\text{eff}}) = 2/3$. Instead of taking only σ_e we take a *flux weighted mean opacity* $\bar{\kappa}$ which contains both electron scattering and line opacities in this work. Here we essentially follow the scheme of the modified Castor, Abbott and Klein theory (Castor *et al.* 1975; Pauldrach *et al.* 1986; Kudritzki *et al.* 1989) and refer to them for the notation.

The flux weighted mean opacity we adopt can be obtained from the radiation-driven wind theory as $\bar{\kappa} = \sigma_e[1 + M]$, where M is the so-called force-multiplier, which gives the radiative acceleration due to the lines in units of $g_{\text{Eddington}}$. According to Kudritzki *et al.* (1989) the force multiplier can be written as

$$M \left(\rho, v, \frac{dv}{dr}, r, n_e \right) = k \left(\frac{\sigma_e \rho v_{\text{th}}}{dv/dr} \right)^{-\alpha} \left(\frac{n_e}{W(r)} \right)^{\delta} CF \left(r, v, \frac{dv}{dr} \right)$$

where n_e is the electron density, v_{th} the thermal velocity of protons, W the dilution factor and CF is the correction factor resulting from nonradial streaming photons. The choice of the parameters k , α and δ will be discussed below. The correction factor CF and $\frac{n_e}{W(r)}$ are computed according to the “cooking recipe” of Kudritzki *et al.* (1989) while σ_e is evaluated consistently with the ionization obtained in the outermost layers of the model.

The optical depth is given by

$$\tau(r) = \int_r^{\infty} \bar{\kappa} \rho dr = \int_r^{\infty} \sigma_e \rho dr + \int_r^{\infty} \sigma_e M \rho dr \equiv \tau_e + \tau_{\text{lines}}.$$

With the velocity law given above an analytic expression for τ_e can be found (e.g. Baschek *et al.* 1991). The same holds for τ_{lines} in the case of $CF = 1$, $\delta = 0$ for which

$$\tau_{\text{lines}}(r) = k \sigma_e^{1-\alpha} v_{\text{th}}^{-\alpha} \left(\frac{|\dot{M}|}{4\pi} \right)^{1-\alpha} v_{\infty}^{2\alpha-1} R^{\alpha-1} \beta^{\alpha} \frac{1}{\gamma} \left[1 - \left(1 - \frac{R}{r} \right)^{\gamma} \right]$$

where $\gamma = 2\alpha\beta - \alpha - \beta + 1$. These expressions can be used to estimate the contribution τ_{lines} to the optical depth τ . Finally the effective radius is obtained from the optical-depth radius $\tau(R_{\text{eff}}) = 2/3$ and this gives the desired effective temperature through the Stefan-Boltzmann law.

We adopted the following line force parameters: $k = 0.124$, $\alpha = 0.64$, $\delta = 0.07$ taken for $T = 50000$ K from

Pauldrach *et al.* (1986) and $v_{\infty} = 2000 \text{ km s}^{-1}$, $\beta = 2$. Although the radiation-driven wind theory does not predict enough force to explain the strong mass-loss of WR stars, the opacities obtained with this procedure are more realistic than the use of only electron scattering opacity and thus give better estimations of the extensions of WR atmospheres.

The correction-scheme described above was applied to the WR phases. The resulting effective temperature is given in the tables in column 4 on the first line of each model. For the WR stars the uncorrected temperature (“core temperature”) is also given in the tables in column 2 on the second line of each model.

The effective temperatures obtained with such a correction (cf. Maeder 1990; Schaerer 1990) cover the domain of observed WNL, WNE and WC stars. The well-defined tracks in the HR diagram (cf. Figs. 5, 6 and 7) followed by WNE and WC stars, independently of their initial mass, result from the T_{eff} correction. It is explained by the mass-luminosity relation (cf. Maeder 1983; Langer 1989) and the $\dot{M}$ vs. M relation. Thus the higher L the larger is $\dot{M}$, which gives a large correction in T_{eff} and shifts the star rightwards in the HR diagram. Together with relations for the luminosity, radius and surface compositions this gives raise to an important number of correlations for WNE and WC stars which will be studied in the near future.

3. Content of the tables.

Tables 1 to 44 contain the data of the models in the range of initial masses from 120 to 0.80 $M_{\odot}$ with metallicities $Z = 0.020$ and $Z = 0.001$. Each table is labelled by the initial stellar mass considered and the value of Z . For 1.25 $M_{\odot}$ we give one table computed with overshooting (Tab. 18 at $Z = 0.02$ and 40 at $Z = 0.001$) and one without overshooting (Tab. 19 at $Z = 0.02$ and 41 at $Z = 0.001$). The differences are about 20 – 25% for the MS lifetimes. If a choice has to be made, the values from models without overshooting can be taken. Tables 1A to 6A contain the models data for 120, 85, 60, 40, 25 and 20 $M_{\odot}$ at $Z = 0.020$ with a mass loss rate doubled in post-MS phases (cf. Sect. 2.6).

For each initial mass, 51 models (out of about 1000 to 2000) have been selected to describe the tracks with a sufficient number of points in order to allow significant and accurate interpolations between the tracks. For massive stars ($M > 7 M_{\odot}$), the evolution has been followed up to the end of the C-burning phase. For intermediate mass stars ($5 \geq M/M_{\odot} \geq 2$) the evolution is followed up to the end of the early asymptotic giant branch (E-AGB). For low mass stars ($M \leq 1.7 M_{\odot}$), the evolution is calculated up to the He-flash. As far as possible, corresponding evolutionary stages have the same number in the first column of Tables 1-44. Typically, one has for the following model numbers:

- 1) Beginning of the H-burning phase.
 - 2-10) Central H-content, in mass fraction, $X_c \simeq 0.62, 0.54, 0.46, 0.38, 0.30, 0.22, 0.16, 0.10, 0.06$ respectively.
 - 11) Point with the lowest T_{eff} on the main sequence evolution (except when surface abundances are modified).
 - 13) End of core hydrogen burning.
 - 15-20) First crossing of the HR diagram from blue to red, when present. Otherwise transition towards the beginning of the He-burning phase. Point 20 generally corresponds to a local minimum of the luminosity.
 - 21) Near the beginning of the He-burning phase with typically a central He-content of $Y_c = 0.978$. In the low mass star range ($M \leq 1.7 M_\odot$) points 21 to 51 describe the ascent of the red giant branch, points are listed for approximatively each 0.05 change in $\log L/L_\odot$.
 - 22-30) $Y_c \simeq 0.95, 0.90, 0.85, 0.80, 0.75, 0.70, 0.65, 0.60, 0.55$
 - 31-40) $Y_c \simeq 0.50, 0.45, 0.40, 0.35, 0.30, 0.25, 0.20, 0.15, 0.10, 0.05$
- Some points have been selected outside these values of Y_c when loops occur during the He-burning phase in order to well describe the shape of the loops in the HR diagram
- 41-42) $Y_c = 0.03, 0.01$
 - 43) End of central He-burning
 - 44-45) Typically $\log(T_c) = 8.70, 8.80$ where T_c is the central temperature.
 - 46) Central C-burning has just started by consuming an amount of about 0.002 of central ^{12}C .
 - 51) Central C-exhaustion or very near ($X(^{12}\text{C}) < 10^{-3}$).

For each model the relevant data is given on two lines. On the first line, the model number as defined above, the age, the actual mass, $\log L/L_\odot$, $\log T_{\text{eff}}$ and the surface abundances (in mass fraction) of the indicated elements, namely H, ^4He , ^{12}C , ^{13}C , ^{14}N , ^{16}O , ^{17}O , ^{18}O , ^{20}Ne , ^{22}Ne . The second line of each model gives QCC, the core mass fraction (overshooting included), the uncorrected value of T_{eff} (for WR stars only), the value of $\log(-\dot{M})$, where $\dot{M}$ is the mass loss rate, $\log(\text{central density})$, $\log(\text{central temperature})$, and the central abundances (in mass fraction) of the above elements.

Let us note that the values of T_{eff} have been corrected for the effects of stellar winds as discussed in Sect. 2.7 for stars in WR stage and $\log T_{\text{eff}} \gtrsim 4.1$ (below this temperature the corrections are generally negligible).

4. Short discussion of the main results.

4.1. HR DIAGRAM AND LIFETIMES.

In this paragraph we present some global properties of the HR diagram as they appear from these new stellar models. More specific points concerning the massive stars will be discussed in Sect. 4.2. Detailed discussions of the

effects of overshooting and mass loss in the HR diagram can be found in Chiosi & Maeder (1986 and see references therein), Maeder & Meynet (1987, 1989).

Let us compare Figures 1 and 2 where we can see the changes due to a decrease of the initial metallicity by a factor 20. The main differences between the two sets of models are the following ones:

- 1) the ZAMS at low Z is shifted to the blue with respect to its position at solar metallicity by an amount comprised between 0.04 – 0.10 dex in $\log T_{\text{eff}}$. The maximum of deviation occurs at about $\log L/L_\odot = 2$. At the extremities of the range of luminosities spanned by the present models, due to opacity effects, the differences become smaller (see Sect. 4.2).
- 2) For low mass stars, the point on the ZAMS at low Z is at a much higher effective temperature and luminosity than at solar metallicity. As a numerical example, the differences of the positions for the $1.5 M_\odot$ model amount to 0.13 in $\log T_{\text{eff}}$ and to 0.24 in $\log L/L_\odot$, thus the luminosity of this model during the H-burning phase is enhanced by about a factor of 2 as compared to the evolutionary track computed at $Z = 0.020$. This will explain the large differences in the timescales of the two sets (see below). When the initial mass increases, the differences become less important.
- 3) When metallicity decreases from 0.020 to 0.001, the width of the MS is generally reduced. The differences of the widths between the two sets of models amounts to $(0.2-0.5)M_{\text{bol}}$ in the range of initial masses comprised between 1.5 and $25 M_\odot$. These differences tend to decrease when one moves to the upper part of the MS. In the low mass range on the contrary, the width of the MS increases when metallicity decreases. For the one solar mass model, the width of the MS passes from the value of 0.75 to 1.00 in M_{bol} when Z decreases from 0.020 to 0.001.
- 4) Lower Z content produces more extended blue loops, the effect being particularly important in the lower part of the mass range where the blue loops occur (for initial masses between 2 and $5 M_\odot$). Let us mention that Alongi et al. (1991) have found a reduction of the length of the loops when Z is decreased from the solar value to 0.008 (cf. their models with a mild core overshoot). In order to reproduce the observed length, they had to introduce a new free parameter, the distance of envelope overshoot, whose role is to extend the outer convective envelope towards the interior. Here, without the adjunction of any new parameter, extended blue loops are obtained for a metallicity $Z = 0.001$.
- 5) Finally let us briefly mention that when Z decreases from 0.020 to 0.001, the positions of the red giant branch (RGB), asymptotic giant branch (AGB) and of the red supergiants are shifted to the blue, the He-flash generally occurs at lower luminosity and the convective

core in the 1.25 $M_{\odot}$ computed without overshooting disappears before the end of the H-burning phase.

Let us also compare the present models for solar metallicity with the grid computed by Maeder & Meynet (1989). The following differences can be observed:

- 1) The positions of the ZAMS are slightly different. For stellar masses greater than 2.5 $M_{\odot}$, the new ZAMS is redder by about 0.015 dex in $\log T_{\text{eff}}$ (see Fig. 3). For lower mass stars, a displacement of the ZAMS in the opposite direction is observed. It amounts to 0.020 dex in $\log T_{\text{eff}}$ for $M_{\text{bol}} = +4$.
- 2) In Figure 3, the ZAMS and the envelopes of the main sequences for the two sets of models are represented. The widths of the MS are in very good agreement at the exception of the upper part of the HR diagram where the prominent "paunch" which was present in the interval of 25 to 60 $M_{\odot}$ models in the old set is reinforced, narrowed and displaced towards higher mass models (40 $M_{\odot} \leq M \leq 85 M_{\odot}$) in the new grid (see also Sect. 4.2). The fact that in general the same width for the MS was obtained in the two sets of models is not surprising since, in both case, the overshooting parameter was chosen in order to reproduce the observed location of the top of the MS, feature which is very sensitive to the value of this parameter. The use of the new opacity tables has slightly reduced the overshooting parameter from the value of 0.25, obtained with the Los Alamos opacity tables, to 0.20 as discussed in section 2.5.
- 3) The blueward extensions of the loops occurring during the helium burning phase for stars with initial masses between 2 and 12 $M_{\odot}$ are a little shorter for the new models. This is the expected behaviour if the opacities are increased. The differences are particularly important for the 5 $M_{\odot}$ model for which the extension has been reduced by a factor of two. The luminosities of the loops are also smaller by an amount of about one fourth of a magnitude at the bluest point.
- 4) The positions of the RGB and AGB present no great discrepancies compared to those obtained in previous models. The positions where He-flash occurs are bluer in the new grid by about 0.04 – 0.07 dex in $\log T_{\text{eff}}$. The effective temperatures of the red supergiants are greater in the new grid by a non negligible amount: for the 15 $M_{\odot}$ model the RSG branch is moved towards the blue by about 0.04 dex in $\log T_{\text{eff}}$, the trend being reinforced when one passes from the 15 $M_{\odot}$ to the 25 $M_{\odot}$ model.

To sum up we can say that the differences between the two grids, as they appear from the comparison of the theoretical HR diagrams, are modest. This implies a great similarity of the internal structures between the two sets of models. Some other features may however be different. For instance due to the many improvements brought to the models, the ratios of the mass fractions of ^{12}C to ^{16}O at

the end of the He-burning phase are significantly reduced with respect to those obtained in the old models. In this work, less ^{16}O is produced and more ^{12}C is available for the carbon-burning phase and the ratios $^{12}\text{C}/^{16}\text{O}$ have values between 0.13 to 0.46. These values are well above the range of values obtained in the previous grid of models, where $^{12}\text{C}/^{16}\text{O} = 0.015 - 0.14$. This result has of course strong implications on the stellar yields as derived from these new models.

The lifetimes in the various nuclear phases are given in Table 45 for $Z = 0.02$, in Table 46 for $Z = 0.001$ and Table 47 for the complementary case at $Z = 0.02$ with increased mass loss rates in post MS. Figure 4 shows nicely the behaviour of the lifetimes in the H and He-burning phases. The H-burning phase is counted from the zero-age sequence (point 1 in Tabs. 1-44) to central H-exhaustion (point 13). The He-burning phase is counted from the stage when two thousands of helium in mass fraction has been burnt to central He-exhaustion (point 43) and the C-burning phase from point 43 to 51. Care must be taken in these definitions. If other ones are desired, the values may be derived from Tables 1-44.

We notice great differences in the MS lifetimes between models with $Z = 0.020$ and $Z = 0.001$. For $M > 9 M_{\odot}$, the MS lifetimes at $Z = 0.020$ are smaller by 8 to 13% with respect to models with $Z = 0.001$. The main reason is the higher luminosities of the former, which result from their smaller electron scattering opacities due to their lower hydrogen content. The differences in the core mass fraction are not large enough to make significant effects. For $M < 7 M_{\odot}$, the effect is the opposite one. Due to their much larger opacities and lower luminosities, the models at $Z = 0.020$ have much larger lifetimes than the models at $Z = 0.001$. The difference is 21% at 3 $M_{\odot}$, 30% at 2 $M_{\odot}$, 46% at 1.5 $M_{\odot}$ and 59% at 1 $M_{\odot}$! We may also notice that the lifetimes in the H-burning phase at $Z = 0.020$ for $M = 1.25$ to 2 $M_{\odot}$ are much smaller, for reasons given in Sect. 2, compared to the values given by Maeder & Meynet (1989).

In Tables 45-47, the ratios $t_{\text{He}}/t_{\text{H}}$ of the He- and H-lifetimes are also given. For masses between 7 and 40 $M_{\odot}$, the ratio $t_{\text{He}}/t_{\text{H}}$ is about 10% at $Z = 0.020$ and about 8-10% at $Z = 0.001$. For larger masses, the $t_{\text{He}}/t_{\text{H}}$ ratio becomes larger if the mass loss rates are larger, because in this case there is a sizeable decrease of the luminosity. This is why the values of $t_{\text{He}}/t_{\text{H}}$ are very large (about 20% and up to 34% at 120 $M_{\odot}$) for massive stars with increased $\dot{M}$ -rates in post-MS phases (cf. Tab. 47). For standard $\dot{M}$ -rates at $Z = 0.020$, they raise up to 16%, while at $Z = 0.001$ due to the very low $\dot{M}$ -rates they keep close to 10% even at 120 $M_{\odot}$. It is worth to mention here that the present $t_{\text{He}}/t_{\text{H}}$ are quite consistent with those by Stothers & Chin (1991b), and match the observational data collected by these authors well. For $M \leq 5 M_{\odot}$, due to considerable energy supply from the H-burning shell,

the $t_{\text{He}}/t_{\text{H}}$ ratios are again larger. The ratio of C-burning phase to the duration of the MS phase increases with the initial mass. This phase represents typically 1×10^{-3} to 4×10^{-3} of the MS phase. Attention must be paid here to the fact that the lifetime of the effective C-burning period is very short. Most of the so-called C-phase is spent in the contraction phase following central He-exhaustion.

4.2. MASSIVE STARS EVOLUTION AND WR STARS.

Figure 5 shows the HR diagram of massive stars for $Z = 0.02$ and standard mass loss rates $\dot{M}$ as described in Sect. 2.6, while Figure 6 shows the same but with $\dot{M}$ -rates increased by a factor 2 in post-MS stages (cf. Tabs. 1A to 6A). Figure 7 presents the case $Z = 0.001$. Without entering in all the details about the structure and evolution, we just mention here a few main results and data.

Main sequence: For massive stars, the zero-age sequence of models with $Z = 0.001$ is shifted to the blue by $0.04 - 0.05$ in $\log T_{\text{eff}}$ with respect to the case $Z = 0.020$. This change is much smaller than for low stellar masses (cf. Sect. 4.1) for the following reason. Models with $Z = 0.001$, $Y = 0.243$ have lower bound-free (b-f) and line opacities, but higher electron scattering opacities compared to the models with $Z = 0.02$ and $Y = 0.30$. In massive stars, the relative importance of b-f and line opacities is not as high as in low mass stars and thus the shifts in T_{eff} and L due to b-f and line opacity sources are nearly compensated by the opposite changes due to electron scattering, when one is going from one set of models to the other. Thus the effect is smaller in massive stars.

In Figures 5 and 6 the upper envelope of the main sequence band undergoes about the same shift as the zero age sequence for $M \leq 25 M_{\odot}$. Thus, the widths of the MS band are similar. For $Z = 0.020$, the MS width is very similar to that of the models by Maeder & Meynet (1989) as a result of the choice of the overshooting parameter (cf. Sect. 2.5). However, there is a major difference between Figures 5 and 6: for $M \geq 40 M_{\odot}$, at $Z = 0.020$, the MS band widely extends over the HR diagram, while there is no such extension at $Z = 0.001$. This interesting behaviour was already found by Stothers & Chin (1977, 1985) who have shown that an increase of the opacities in the outer layers of massive stars may produce a MS band covering all the HR diagram. We may thus wonder whether some LBV (luminous blue variables) and blue supergiants are still in the MS band. This would particularly be possible at higher Z , where the MS extension is likely larger.

Supergiants: At $Z = 0.001$, the helium burning phase is mostly spent in the blue supergiant region, as shown by the indications about the central helium content Y_{c} in Figure 6 (cf. Stothers & Chin 1976). At $Z = 0.020$ and for $M \leq 40 M_{\odot}$, helium is mainly burnt in red or yellow supergiants. Such effects are well known and the physical reasons for the redwards and bluewards motions of the

massive stars have been studied elsewhere (cf. Stothers & Chin 1979; Maeder 1981). The increase of $\dot{M}$ at $Z = 0.020$ (cf. Fig. 7) does not significantly modify this situation, but it favours an early bluewards departure towards the WR stage.

Red supergiants should be rarer at $Z = 0.001$ compared to the case $Z = 0.020$; their T_{eff} is also higher due to the much lower opacities. The frequency of red supergiants in galaxies at low Z constitutes an interesting test. Possible differences between models and observations could be assigned either to the $\dot{M}$ vs. Z relation or may be to mixing processes.

Another difference between Figures 5 and 6 is that the blue and yellow supergiants with $Z = 0.001$ are much brighter than those with $Z = 0.020$ for a given initial mass. This is especially visible for $15 M_{\odot}$ where the difference amounts to about 0.5 mag. This is due to opacities, but also to the fact that helium burning is more advanced in the blue supergiants at low Z .

At $Z = 0.020$, models with $M \geq 60 M_{\odot}$ make excursions in the region of LBV. Paradoxically, the mass loss rates in this area of the HR diagram are so high that (within a certain range) their exact values are not critical. Indeed, the main consequence of this huge mass loss is to remove the original stellar envelope and to lead to WR stars. However, at rates of 10^{-3} to $10^{-4} M_{\odot}/\text{yr}$ this lasts only for a very small fraction of the helium burning phase. Thus, whether the LBV phase represents a few thousands or a few hundreds of the He-burning phase does not significantly influence the further evolution in the WR stages.

WR stars: The locations of WNL, WNE and WC stars in the HR diagram with account for the optically thick winds treated with the modified Castor, Abbott & Klein theory (cf. Castor *et al.* 1975; Kudritzki *et al.* 1989) are shown in Figures 5-7. A star is considered to be a WNL when its hydrogen surface abundance $X_{\text{H}} \lesssim 0.4$ with a blue location in the HR diagram ($\log T_{\text{eff}} \gtrsim 4.0$), WNE stars have no hydrogen and do not yet show the products of He-burning, while WC stars show these products.

In the WNL stage, the tracks are nearly horizontal, descending slightly more when the $\dot{M}$ -rates are larger (cf. Fig. 7). WNE stars occupy a band in the HR diagram located to the left of the long WC band. For each mass, the WNE phase occupy a luminosity range just below the termination of the WNL phase. At the beginning of the WNE phase, the T_{eff} strongly decreases due to higher mass loss rates and the consequently thick envelopes.

At the end of the WNE stage, the star is shifted to the WC band due to the higher $\dot{M}$ -rates, cf. Sect. 2.6, where it goes down as the mass further decreases. We know that WR stars obey a mass-luminosity relation (cf. Maeder 1983), but Figures 5 and 7 also show that there are L vs. T_{eff} relations for WNE and WC stars. The explanation is that as the stellar mass is declining in the

WR stage, the $\dot{M}$ -rate also decreases and so does the thickness of the expanding atmosphere, which makes the T_{eff} to increase. Simultaneously, the surface composition is changing as deeper layers are revealed. Thus, there are $M - L - \dot{M} - T_{\text{eff}}$ - composition relations to be expected for WR stars without hydrogen. For now, they have not been well defined observationally even if some trends are present (cf. Smith & Maeder 1989).

At $Z = 0.001$ (cf. Fig. 6), WR stars only occur for models of 85 and 120 $M_{\odot}$ and they are only WNL stars. The further WNE and WC phases are never entered as a result of the large remaining masses. At $Z = 0.020$ (cf. Fig. 5), the 3 WR phases are present. We see that with the larger $\dot{M}$ -rates (cf. Fig. 7), the downwards motion of WR stars is much more important and luminosities as low as $\log L/L_{\odot} \simeq 4$ can be reached. Interestingly, after the He-exhaustion the large energy releases due to the core contraction and the He-burning shell lead the stellar luminosity to go up again.

A few WR stars with luminosities in the range of $\log L/L_{\odot} = 4$ to 5 have been found (cf. Koesterke *et al.* 1991). This favours the models with larger $\dot{M}$ -rates rather than the standard ones. This suggests that the true mass loss rates for massive stars are on average certainly as large or even larger (within about a factor of 2) than the standard values of the mass loss rates (cf. de Jager *et al.* 1988). In particular we could also suspect that at some stages (may be WNL or the supergiants stages) the $\dot{M}$ -rates are larger in order to also produce some WNE stars with low luminosities. Table 48 shows the lifetimes in the WR (total), WN and WC phases. In agreement with previous works (cf. Maeder 1991), we notice a strong increase of the WR lifetimes with metallicity and $\dot{M}$ -rates. For each Z -value in Table 48, the last mass value indicates the approximate value of the lower mass limit for forming WR stars. Very interestingly, the lifetimes at $Z = 0.020$ with increased $\dot{M}$ -rates, which also better fit the lower value of the observed luminosities, have values such as to also well account for the observed WR/O ratios (cf. Maeder 1991). Work is now in progress, where the various relations $M - L - \dot{M} - T_{\text{eff}}$ - composition are established for WR stars, and by comparison with the observations, these relations will be used to better constrain the basic parameters of Wolf-Rayet stars.

Acknowledgements.

We express our thanks to Drs. Forrest J. Rogers and Carlos A. Iglesias for providing us with their new opacity data.

FIGURE 2. Same as in Figure 1 for an initial metallicity $Z = 0.001$.FIGURE 1. Theoretical HR diagram for the ensemble of the calculated models for solar metallicity with an overshooting parameter $\alpha_{\text{over}} = d_{\text{over}}/H_p = 0.20$. The slow phases of nuclear burning are indicated by hatched areas. At $1.25 M_{\odot}$, the model shown in the figure is the one without overshooting. The spectral types are taken from Kudritzki & Hummer (1986) and from Böhm-Vitense (1981).

FIGURE 3. ZAMS and envelopes of the main sequences for the present set of models at solar metallicity and for the models computed by Maeder & Meynet (1989) are indicated in the theoretical HR diagram. A few evolutionary tracks from the present grid of models are also represented, for purpose of clarity, only the first part of the evolutionary track for the $60 M_{\odot}$ has been drawn.

FIGURE 4. The logarithm of the lifetimes in years for the H and He-burning phases are represented in function of the logarithm of the initial mass expressed in solar units, for the two sets of models at $Z = 0.020$ and $Z = 0.001$. At $1.25 M_{\odot}$, the lifetimes for the models with and without overshooting are shown.

FIGURE 5. The HR diagram for massive stars with $Z = 0.020$ and standard mass loss rates. The locations of WNL, WNE and WC stars are indicated, as the well as the values of central helium content Y_c during the He-burning phase; the values 0.97, 0.90, 0.80, 0.70, 0.60, ..., 0.10, 0 are generally indicated by a small bar on the track.

FIGURE 6. The HR diagram for massive stars with $Z = 0.001$. Same remarks as for Figure 5.

FIGURE 7. the HR diagram for massive stars with $Z = 0.020$ and mass loss rates increased by a factor of 2 in post-MS phases. Same remarks as for Figure 5.
